δ\(^{15}\)N Values in *Crassostrea virginica* Shells Provides Early Direct Evidence for Nitrogen Loading to Chesapeake Bay

H. D. Black\(^1,2\), C. F. T. Andrus\(^3\), W. J. Lambert\(^1\), T. C. Rick\(^3\) & D. P. Gillikin\(^4\)

*Crassostrea virginica* is one of the most common estuarine bivalves in the United States’ east coast and is frequently found in archaeological sites and sub-fossil deposits. Although there have been several sclerochronological studies on stable carbon and oxygen isotopes in the shells of this species, less is known about δ\(^{15}\)N values within their shells, which could be a useful paleoenvironmental proxy to assess estuarine nitrogen dynamics. Modern *C. virginica* samples were collected in Chesapeake Bay for comparison with archaeological shells from nearby sites ranging in age from ~100 to 3,200 years old. Left valves were sampled by milling the hinge area and the resulting powder was analyzed for %N and δ\(^{15}\)N values. Comparison of δ\(^{15}\)N values between *C. virginica* shells shows relatively constant values from ~1250 BC to ~1800 AD. After ~1800 AD, there are rapid increases in \(^{15}\)N enrichment in the shells, which continue to increase in value up to the modern shell values. The increase in δ\(^{15}\)N values is evidence of early anthropogenic impact in Chesapeake Bay. These results corroborate the observation that coastal nitrogen pollution occurred earlier than the 19th century and support the use of oyster shell δ\(^{15}\)N values as a useful environmental proxy.

Anthropogenic pollution, especially nitrogen, is a major concern in coastal estuaries. Increased nitrogen loading can potentially lead to eutrophication, which can cause anoxic conditions in water bodies and die-off events of marine organisms in dead zones. Since the 1970s, regulations governing nitrogen inputs have been introduced, but in order for these policies to be effective, it is imperative to know base levels of nitrogen in the area. In most cases, however, base levels before anthropogenic influences began are unknown. If mollusk shells serve as a paleoenvironmental proxy for environmental N levels using stable nitrogen isotope (δ\(^{15}\)N) values, scientists could generate a base level of nitrogen by studying the record of nitrogen isotopes stored in the shells, as well as how nitrogen sources and concentrations have fluctuated over time.

Bivalve shell geochemistry is commonly used to assess environmental parameters at the time the shell grew, such as sea surface temperature and salinity. The eastern oyster *Crassostrea virginica* has large environmental tolerances; able to survive significant variations in temperature (20–45°C), salinity (0–42 psu), and food supply. Since they are sessile filter feeders in physical contact with water, their soft tissues and shells can record environmental changes by incorporating organic materials from the surrounding water body. *C. virginica* shells are primarily calcitic, but have a thin aragonite layer in the ligostracum and muscle scar. This species has previously been used for numerous stable isotope studies on stable carbon and oxygen isotopes within the shell (e.g. refs 17–20), and recently has been introduced as a possible paleoenvironmental proxy for environmental N levels by analyzing the shell δ\(^{15}\)N values. Anthropogenic nitrogen sources, specifically sewage and industrial pollutants, are typically more \(^{15}\)N enriched than non-anthropogenic sources, making it possible to trace nitrogen inputs into estuaries by studying the δ\(^{15}\)N values in the tissue and shell organic fraction.

Unlike the soft tissue samples that were traditionally used in biological and environmental studies of mollusks, shell material can potentially serve as a better proxy for past conditions due to the increased chance of
preservation over time. Mollusk shell material accretes sequentially, sometimes in annual growth layers, which could potentially be used as a high resolution temporal proxy for historical nitrogen levels, as well as creating a time-series of nitrogen loading over the life of the organism. Furthermore, the shell material is never metabolized, so it can record the environmental conditions over a longer period of time than soft tissues. It has previously been established that the calcite shell organic fraction chemistry reflects that of the organisms’ soft tissues, with minimal variability in δ¹⁵N values (~0–2‰) between the soft tissues and shell material.

Here we determine if C. virginica shells record historical evidence of N levels in the Rhode River basin in Chesapeake Bay during the late Holocene to assess when anthropogenic N loading began. In doing so, we seek to better validate and establish this novel environmental proxy. To test for Chesapeake Bay nitrogen in historic and prehistoric mollusk shells, we sampled archaeological and modern (living) oysters from the Rhode River Estuary at the Smithsonian Environmental Research Center in Edgewater, Maryland (38°53′N 76°32′W) (Fig. 1).

Our archaeological samples date to the Woodland Period (including the Early [1200–500 BC], Middle [500 BC–AD 900], and Late [AD 900–1600]), and the 18th and 19th centuries. During the Woodland period in the Chesapeake, Native American peoples practiced a largely hunting and gathering lifestyle and their populations appeared to expand during the Middle Woodland and especially during the Late Woodland, when maize agriculture appeared in parts of the region. European colonization intensified in the area in the 17th century, with colonial settlements clearing the forests and establishing large plantations on pristine agricultural land. During the 19th century, industrialization rapidly increased in the eastern US and continues today.

Although Native Americans practiced agriculture and cleared forests in the region, these impacts were more localized and less widespread than the major landscape clearance efforts of Euro-American colonists and later peoples from the 17th century onward. Historic period land clearance resulted in significant sedimentation, and likely nutrient loading, into the Bay. These data lead Kirby and Miller to hypothesize that an increase in observed growth rates of oysters from archaeological sites on the Potomac and Patuxent rivers during the 18th and 19th century may have been due to an increase in planktonic primary productivity from nutrient loading during early eutrophication. The initial period of faster growth was later followed by a size decrease that they speculate was from intensive eutrophication and environmental deterioration, such as increased occurrences of harmful algae and parasitic disease after AD 1860. They speculate that other environmental changes, such as changes in water chemistry and an increase in the degree of fishing disturbances, in Chesapeake Bay during this time could affect the growth rate of C. virginica, but these environmental conditions are unlikely to cause as significant of an effect in shell growth rates as eutrophication. Our δ¹⁵N data provide a means to test this hypothesis and to help develop a novel proxy for assessing N in marine shellfish.
Results

One-way ANOVA tests for δ¹⁵N values between time periods produced an F-value of 297.3 and a significance of \( p < 0.001 \) at \( \alpha = 0.05 \) (data summarized in Table 1). This indicates that the sample variance between different time periods was greater than the variance within time periods. A Tukey Post Hoc test yielded results that show that archaeological samples from the Early Woodland (1250–800 BC) are significantly different from Middle Woodland (500 BC–AD 900), 19th century, and modern samples. Archaeological samples from the Middle Woodland were significantly different from Early Woodland, latter 19th century, and modern samples. Archaeological samples from the Late Woodland (AD 900–1600), 18th and early 19th century were significantly different from latter 19th century and modern samples. Later 19th century and modern shells were significantly different from all other time periods (Fig. 2).

The F-value calculated by a one-way ANOVA for percent nitrogen (%N) was 34.8 with a significance of \( p < 0.001 \) at \( \alpha = 0.05 \). A Tukey Post Hoc test yielded results that show archaeological samples from the Early, Middle, and Late Woodland periods were significantly different only from the modern samples (data summarized

Table 1. δ¹⁵N (‰ AIR) values for the periods sampled [Archaeological periods Early Woodland (Site 18AN308), Middle Woodland (Site 18AN285), Late Woodland (Site 18AN287), 18th Century (Site 18AN839), 19th Century (Site 18AN1323), and Modern]. Precision (1σ) was better than 0.09‰. All dates calibrated using OxCal 4.2\textsuperscript{15,36} and applying a standard reservoir correction of 97 ± 18 years for all shells. Details for all site chronologies are provided in Rick et al.\textsuperscript{21}. Ages given in text and figures are based on radiocarbon dates, stratigraphic position, and presence of time sensitive artifacts (see refs 21 and 37).

Figure 2. Plot of δ¹⁵N (‰ AIR) values for modern and archaeological C. virginica shells. Precision (1σ) was better than 0.09‰ based on analysis of multiple standards over a range of isotopic values.
in Table 2). The 18th and 19th century samples were only significantly different from the modern samples and the modern samples were significantly different from all other time periods (Fig. 3).

Discussion

Our results indicate increased N loading to Chesapeake Bay started as early as the 19th century and substantially increased to the present. Time-series comparisons of the sampled shells display distinct trends, with both %N and δ15N values following a roughly exponential curve with higher concentrations of N and more 15N enriched shells occurring in the 19th century and modern samples. The %N remains more constant than the δ15N values, but increases ~0.07% from the 18th century to modern shells (Fig. 3). The δ15N values remain relatively constant from the Early Woodland until the first part of the late 18th to 19th century (i.e., 1750–1800) but then increase ~3‰ from the late 18th century to mid late 19th century (i.e., 1850–1900) (Fig. 2). There was another substantial increase in δ15N values (~1‰) between the mid to late 19th century shells and the modern collected shells, which is correlated to a 10-fold increase in reactive N species globally from 1860 to 199035.

δ14N values in mollusk shells have been shown to faithfully track the values in soft tissues and ambient POM26,27,36. In contrast, variation in mollusk shell %N has not been validated as a meaningful proxy for ambient N concentrations and additional analysis of modern samples is required before interpretation of such data is possible. Although the relatively constant %N suggests little to no N loss from the shells over time, our discussion will focus solely on δ15N values.

Figure 3. Plot of percent nitrogen values for modern and archaeological C. virginica shells.
We argue that the trends in δ¹⁵N physically disintegrate. Finally, the close correspondence between our data and the sediment core-based proxies during a series of prehistoric cooking methods studies unless the shell was heated to the point at which it began to mix with estuarine waters before deposition, so it could potentially record higher δ¹⁵N values at an earlier time period. Another possibility for the timing differences between this study and Bratton et al. is due to the dating methods used. While our study solely used ¹⁴C from corrected and calibrated archaeological oysters, Bratton et al. used pollen stratigraphy, ¹³C of shell material within the cores, and the short-lived radiotopes Cs and Pb within recently deposited sediment. Since pollen was primarily used to relatively date the sediment, it is possible that the absolute dates obtained by their ¹⁴C analysis could permit larger error in the dating due to reworking and bioturbation of the sediments.

During the 19th century, population sizes and industrialization in the northeast US expanded exponentially, which likely had a profound impact on the ecological health of the Bay. Between 1830 and 1880, over 80% of the forest surrounding Chesapeake Bay had been cleared, which, in combination with plowing for agriculture, greatly increased the sediment accumulation in the bay. Research at sites on the Potomac and Patuxent rivers documents this trend in detail, with oysters first increasing in size during the 18th and early 19th centuries and then decreasing dramatically after AD 1860, perhaps from intensive eutrophication. It has been suggested that the degree of organic matter loading into Chesapeake Bay has significantly increased within the last two centuries, but Cornwell et al. did not determine substantial increases in N deposition within the sediment, which could be due to increased algal blooms in the water column and metabolic activity of estuarine organisms. Our data support this hypothesis, providing the first direct evidence of N loading in this location of the bay during the 19th century, particularly in the latter half of the 19th century.

The potential effects of diagenetic alteration of %N and δ¹⁵N values must be considered. Loss of shell organic matter, and consequently N, likely occurs after burial and may be evident in the %N trends noted in our study. We argue, however, that such loss would not explain the observed δ¹⁵N trends. First, the observed trend in δ¹⁵N values would require preferential loss of ¹⁵N, which is contradictory to the kinetics of stable isotopes. Secondly, it is difficult to imagine why diagenetic influence of N isotopes would stop in pre-seventeenth century shells, and even reverse to some extent in the earliest samples. Third, Black was not able to influence shell δ¹⁵N values during a series of prehistoric cooking methods studies unless the shell was heated to the point at which it began to physically disintegrate. Finally, the close correspondence between our data and the sediment core-based proxies of anthropogenic N noted above indicates that the shell data trends accurately follow levels of environmental N. We argue that the trends in δ¹⁵N values noted in this study are primarily the result of changes in the sources contributing to the oysters’ habitat. The source for the somewhat higher δ¹⁵N values in the Early Woodland samples is not readily apparent.

This study demonstrates the potential utility of shell δ¹⁵N proxies. The abundance of this and similar species in archaeological sites worldwide suggests that detailed records of anthropogenic N impacts can be created from shell midden deposits. Such baseline data are valuable not only in addressing modern pollution concerns, but also in assessing the extent of ancient human habitation, land-use, agricultural practice, and related activities. This approach may be less expensive than sediment core analysis and therefore permit wide geographic coverage to facilitate regional N reconstructions. Additionally, archaeological contexts may allow reliable age control of samples, which is sometimes difficult in cores with disturbed sediments. Sclerochronological shell sampling also permits seasonal analysis of δ¹⁵N values in large, fast growing species, which provides even more detailed information. Further research is needed to better assess the variability of shell %N data, the impacts of diagenesis and prehistoric cooking methods, and the possible transport of shells before burial.

For the δ¹⁵N values in C. virginica shells from Chesapeake Bay, there are significant changes in δ¹⁵N values of the shells over time. The δ¹⁵N values remain relatively constant from ~3,200 years ago until 1750–1800, but significantly increase after 1850 to the live-collected shells. While there is a possibility that diagenetic processes may have influenced these data, the sharp increase in δ¹⁵N values between ~1750–1800 and 1850–1900 appears to be primarily due to the industrial revolution, animal wastes, and soil erosion. The subsequent increases from 1850 to 2013 are due to a significant increase in human population, synthetic fertilizer use, sewage discharge, erosion,
and other anthropogenic pollution sources in Chesapeake Bay over the last two centuries. Different N pollutants have varying δ¹⁵N values (i.e., animal wastes range from ~10–20‰ and synthetic fertilizer ~0‰), which explains the large increase in δ¹⁵N values between ~1750–1800 and 1850–1900 and the smaller increase from ~1850–1900 to modern samples. Between ~1750–1800 and 1850–1900, the main N pollutants in Chesapeake Bay were isotopically enriched, leading to a significant increase in δ¹⁵N values from earlier periods. The widespread use of synthetic fertilizers in the 20th century likely caused the reduced increase in δ¹⁵N values between ~1850–1900 to modern samples since synthetic fertilizer has more depleted δ¹⁵N values than earlier sources while increasing the %N in the Bay.

Methods

Oyster shell samples were collected from six different archaeological sites within the Rhode River Estuary of Chesapeake Bay (Fig. 1). Researchers with the Smithsonian Institution collected archaeological samples while excavating shell middens in the region²¹,³⁷. Modern oyster samples were collected from an oyster reef located adjacent to one of the archeological sites and in relatively close proximity to the other archaeological sites. Ninety archaeological shell samples ranging in age from ~100 to 3,200 years old and thirty modern shell samples were analyzed for %N and δ¹⁵N values. The ancient shells were all well preserved and robust (i.e., limited taphonomic effects, no noticeable alteration of color of the shell or ligament scar, and non-chalky texture). The soft tissues were removed from the modern shells and the shells were cleaned using DI water and a soft bottle-brush followed by five minutes of ultrasonic cleaning. The shells were dried overnight at room temperature. The left valve of each shell sample was bisected along the longest axis using a slow-speed diamond-wafering saw. Each shell was subsampled using a hand held micro-drill. In order to create a lifetime average of the %N and δ¹⁵N values, a transect was drilled in cross-section through the resilifer to a depth of approximately 2 mm (Fig. 4). No carbonate powder from the exterior surface of any valve was sampled. Gillikin et al.²⁷ has shown that the oxidative cleaning required for coral and foraminifera samples is not required for dense bivalve shells. The powdered samples were stored in 4.5 mL round-bottomed borosilicate vials until elemental analyzer –isotope ratio mass spectrometry (EA-IRMS) analysis.

To obtain comparable amounts of nitrogen (i.e., mass spectrometer peak area in millivolts (mV)) between the modern and archaeological shell samples, different masses were used. Between 34–35 mg of powdered samples of modern shells were transferred to 5 × 9 mm tin capsules and 100–110 mg of archeological shells were transferred to 9 × 10 mm tin capsules. The samples were analyzed in the Alabama Stable Isotope Laboratory, in the Department of Geological Sciences at the University of Alabama. Determinations for %N and δ¹⁵N values were made using a Costech ECS 4010 elemental analyzer (EA) coupled to a Thermo Delta V isotope ratio mass spectrometer without acid pre-treatment of the samples following Versteegh et al.⁴⁵. The EA was fitted with a carbon trap [glass trap (Costech part no. 071121) filled with CO₂ absorbant (Costech part no. 021020)] to remove CO₂ and operated with a combustion temperature of 1020°C (reduction column = 650 °C).

Figure 4. (A) Image of disarticulated valves of C. virginica. (B) Cross section of C. virginica through the resilifer. The red line represents the micro-drilled transect.
The $\delta^{15}$N data are reported in parts per mil (‰) vs. AIR. Delta notation is calculated using the equation 

$$\delta^{15}N = \left( \frac{R_{\text{sample}} - R_{\text{standard}}}{R_{\text{standard}}} \right) \times 1000.$$ 

Precision (1σ) was better than 0.09‰ based on analysis of two standards over a range of isotopic values (ammonium sulfate standard IAEA-N-2; $\delta^{15}N = 20.3$‰) and Elemental Microanalysis high organic sediment standard B2151; $\delta^{15}N = 4.4$‰. Two elemental standards, acetanilide (%N = 10.36‰) and B2151 (%N = 0.5‰), were used to build the calibration curve for each run and check for accuracy, respectively. Thirty-four samples were analyzed in duplicate with precision better than 0.07‰. One-way ANOVA and Tukey Post Hoc tests were completed on the shell samples based on time period to determine if there were any statistically significant differences between periods over time.
