The IceCube neutrino telescope at the South Pole has measured the atmospheric muon neutrino spectrum as a function of zenith angle and energy in the approximate 320 GeV to 20 TeV range, to search for the oscillation signatures of light sterile neutrinos. No evidence for anomalous as a function of zenith angle and energy in the approximate 320 GeV to 20 TeV range, to search for the oscillation signatures of light sterile neutrinos. No evidence for anomalous

\[ \sin^2 2\theta_{24} \leq 0.02 \text{ at } \Delta m^2 \sim 0.3 \text{ eV}^2 \text{ at the 90% confidence level. The allowed region from global analysis of appearance experiments, including LSND and MiniBooNE, is excluded at approximately the 99% confidence level for the global best-fit value of } |U_{e4}|^2. \]

DOI: 10.1103/PhysRevLett.117.071801
Introduction.—Sterile neutrinos with masses in the range $\Delta m^2 = 0.1-10$ eV$^2$ have been posited to explain anomalies in accelerator [1–3], reactor [4], and radioactive source [5] oscillation experiments. Several null results [6–10] restrict the available parameter space of the minimal $3 + 1$ model, which assumes mixing of the three active neutrinos with a single sterile neutrino, resulting in three light and one heavier mass state. Global fits to world data [11–13] demonstrate that there remain regions of allowed parameter space around the best-fit point of $\Delta m^2 = 1$ eV$^2$ and $\sin^2 2\theta_{24} = 0.1$. A consequence of these models is the existence of $\nu_\mu$ ($\bar{\nu}_\mu$) disappearance signatures, which are yet to be observed.

Atmospheric neutrinos produced in cosmic-ray air showers throughout the Earth’s atmosphere are detected by IceCube [14]. To mitigate the large atmospheric muon background, only upgoing neutrinos are selected. For these trajectories, the Earth acts as a filter to remove the charged particle background. At high neutrino energies, the Earth also modifies the neutrino flux due to charged current and neutral current interactions [15]. At $E_\nu > 100$ GeV, oscillations due to the known neutrino mass splittings have wavelengths larger than the diameter of the Earth and can be neglected.

A previous measurement of the atmospheric flux in the sub-TeV range, performed by the Super-Kamiokande experiment, found no evidence for anomalous neutrino disappearance [7]. This Letter reports the first searches for ($\nu_\mu + \bar{\nu}_\mu$) disappearance in the approximate 320 GeV to 20 TeV range, using two independent analyses each based on one-year data samples from the IceCube detector [16,17]. In this energy regime, sterile neutrinos produce distinctive energy-dependent distortions of the measured zenith angle distributions [18], caused by resonant matter-enhanced oscillations during neutrino propagation through the Earth.

This MSW-resonant effect depletes antineutrinos in $3 + 1$ models (or neutrinos in $1 + 3$) [18,19]. Additional oscillation effects produced by sterile neutrinos include vacuumlike oscillations at low energies for both neutrinos and antineutrinos, and a modification of the Earth opacity at high energies, as sterile neutrinos are unaffected by matter. These effects lead to detectable distortions of the flux in energy and angle, henceforth called “shape effects,” in IceCube for mass splittings in the range $0.01$ eV$^2 \leq \Delta m^2 \leq 10$ eV$^2$ [20–27].

Atmospheric neutrinos in IceCube.—Having crossed the Earth, a small fraction of upgoing atmospheric neutrinos undergoes charged current interactions in either bedrock or ice, creating muons that traverse the instrumented ice of IceCube. These produce secondary particles that add Cherenkov light, which can be detected by the Digital Optical Modules (DOMs) [28–30] of the IceCube array. The full detector contains 5160 DOMs on 86 strings arranged with string-to-string spacing of approximately 125 m and typical vertical DOM separation of 17 m.

The analysis detailed in this paper, referred to as IC86, uses data from the full 86-string detector configuration taken during 2011–2012, with upgoing neutrinos selected according to the procedure developed in [16,31]. The sample contains 20,145 well-reconstructed muons detected over a live time of 343.7 days. A total of 99.9% of the detected events in the data sample are expected to be neutrino-induced muon events from the decays of atmospheric pions and kaons. The flux contribution from charmed meson decays was found to be negligible [16,32], as was the contamination of upgoing atmospheric neutrinos with the spectrum and rate measured by IceCube [16]. A complementary analysis, referred to as IC59 and discussed later, was performed using a sample of 21,857 events observed in 348.1 days of data taken with an earlier 59-string configuration of the detector from 2009–2010 [17].

Since muon production is very forward at these energies, the muon preserves the original neutrino direction with a median opening angle following $0.7$ degrees $\times (E_\nu/\text{TeV})^{-0.7}$ [33]. The muon zenith angle can be reconstructed geometrically with a resolution of $\sigma_{\cos(\theta_M)}$ varying between 0.005 and 0.015 depending on the angle. Because of energy sharing in production and radiative losses outside the detector, the detected muon energy is smeared downward from the original neutrino value. Muon energy is reconstructed based on the stochastic light emission profile along the track [16,34] with a resolution of $\sigma_{\log(E_\mu/\text{GeV})} \sim 0.5$.

To search for shape effects [22,23,25,26], including the MSW and parametric resonances, the analyses compare the predicted observable muon spectrum for a given incident neutrino flux and oscillation hypothesis with data. Flavor evolution in the active and sterile neutrino system can be calculated by numerical solution of a master equation [15,35]. For IC86, this calculation is performed using the $\nu$-SQuIDS software package [36,37], while the IC59 analysis approximates the oscillation probability by solving a Schrödinger-like equation using the NuCraft package [38]. This approximation is accurate to better than 10% below $\Delta m^2 \approx 5$ eV$^2$, where Earth-absorption effects can be neglected. Figure 1 (top and center) shows the predicted depletion of events for the global $3 + 1$ best-fit point in the distribution of reconstructed variables from the IC86 analysis; in this case the large depletion is dominated by the parametric resonance.

Data analysis and systematic uncertainties.—To search for sterile neutrino oscillations we calculate the negative of a binned Poissonian log likelihood (LLH) for the data given each sterile neutrino hypothesis on a fine grid in the $[\log(\Delta m^2), \log(\sin^2 2\theta_{24})]$ hypothesis space. In the IC86 analysis, the data are histogrammed on a grid with ten bins in energy ranging from 400 GeV to 20 TeV, and 21 linearly
uncertainties in the spectral index of the flux. The term $\phi_k$ captures 
the contribution by the neutrinos that originate from pion and kaon 
decays in cosmic-ray showers. This prompts us to introduce an overall 
fitting parameter in the space to produce unified confidence intervals 
and similarly for antineutrinos with a relative flux

$$\frac{d\gamma}{dE} \left( \phi_k + \phi_\pi \right) L_0 N = (\cos \theta)^{\Delta \gamma \gamma}$$

Systematic uncertainties are treated by introducing both continuous 
and discrete nuisance parameters, which are robust in the sense that 
the LLH values are compared to the minimum

The first column indicates the Gaussian width of a prior if 
introduced for the parameter in the analysis (see[40] for details).
The second column is the overall flux normalization uncertainty, 
which is included to the atmospheric flux template. The third column 
indicates the Gaussian width of a prior if 40% was applied to the 
Normalization parameter in the analysis. The numbers in parentheses show the number of 
discrete variants used. Full descriptions are given in the text.
it as a linear function, \( F(\delta) \), which is obtained by fitting fluxes calculated with different atmospheric profiles generated within constraints imposed by temperature data from the AIRS satellite [42].

The central flux prediction for the analysis is the HKKM model with H3a knee correction [43–45]. Additional flux variants are calculated using the analytic air shower evolution code of [46–48]. The cosmic spectrum variants considered are the Gaisser-Hillas [45], Zatsepin-Sokolskaya [49], and Poly-gonato models [50]. The hadronic models considered are QGSJET-II-4 [51] and SIBYLL2.3 [52]. For each combination of hadronic and primary model, fluxes calculated in various atmospheric density profiles are used to derive the \( F(\delta) \) parametrization.

**Neutrino propagation and interaction uncertainties.**—Two sets of neutrino propagation uncertainties are treated in the search. Neutrino oscillation and absorption effects both depend on the Earth density profile along the neutrino trajectory, which is parametrized by the PREM model [53]. Uncertainties in the Earth composition and density are accounted for by creating perturbations of the PREM and repropagating the neutrino flux. The PREM variants are constructed under the constraints that the Earth mass and moment of inertia are preserved, that the density gradient is always negative in the core and mantle regions, and that the local perturbation is never more than 10%. The effects of the Earth model uncertainty on the final propagated neutrino spectrum are incorporated by minimizing over nine discrete perturbed models.

A further propagation uncertainty is the neutrino charged-current cross section that, at these energies, is dominated by DIS. The uncertainty in the cross sections arises from parton distribution function (PDF) uncertainties. A parametrization of the cross-section uncertainty uses calculations [54] (see also [55]) based on three different PDF sets: HERAPDF [56], CT10 [57], and NNPDF [58]. In each case, simulated neutrino interactions are reweighted using true neutrino energy and inelasticity given calculated doubly differential cross sections, and the analysis fit is run using the weighted sample.

**Detector and ice uncertainties.**—The absolute optical module photon collection efficiency, \( e \), has been measured in the laboratory [30]. However, shadowing by the DOM cable and unknown local optical conditions after deployment introduce an uncertainty in the optical efficiency in situ, leading to uncertainty in the detected energy and angular event distribution. Here \( e \) is treated as a continuous nuisance parameter and reweighting techniques are used to correct Monte Carlo distributions to arbitrary values. We follow the method developed in [16,31], implementing a penalized spline [59] fitted to Monte Carlo data sets generated at various DOM efficiency values. Variability of the optical efficiency induces changes in the detector energy scale. In practice, the best-fit value is tightly constrained by the position of the energy peak in the final sample.

The IceCube ice model applied in this analysis has nearly a thousand free parameters that are minimized in an iterative fit procedure using light-emitting diode flasher data [60]. The model implements vertically varying absorption and scattering coefficients across tilted isochronal ice layers. The fit procedure yields a systematic and statistical uncertainty on the optical scattering and absorption coefficients in the ice, as well as a larger uncertainty on the amount of light deposited by the LED flashers. This larger uncertainty was later reduced by introducing azimuthal anisotropy in the scattering length into the ice model, which may result from dust grain shear due to glacial flow [61]. We use the model described in [60] as the central ice model, and then use the model with anisotropy [61] as an alternative to assess the impact of this effect. We also incorporate models with 10% variations in the optical absorption and scattering coefficients to account for the uncertainty on those parameters. A full Monte Carlo sample is created for each model variation.

The ice column immediately surrounding the DOMs has different optical properties than the bulk ice due to dissolved gases that are trapped during the refreezing process following DOM deployment. This introduces additional scattering near the DOM and has a nontrivial effect on its angular response [60]. To quantify this effect on the final event distribution, a comparison is made between the extreme case of the DOM assumed to have its laboratory-derived angular response vs the nominal hole ice model as discrete ice model variants.

**Results.**—The analysis detailed here was developed with 90% of the data sample held blind, and unblinding was a multistep process. The agreement of MC simulations based on the no-sterile-neutrino hypothesis (corresponding to more than 360 years of simulated data) with data was evaluated using one-dimensional energy and zenith angle distributions, which wash out the resonance signature of sterile neutrinos (Fig. 2). Good data-MC (sample) consistency was observed and no nuisance parameter was found to have a significant pull outside of its prior. Other comparisons, insensitive to the sterile neutrino signature, were made by examining subsets of the data split by the reconstructed azimuthal track angle, and by event center of gravity. No significant data-MC (sample) discrepancies were observed. The full event distribution in the two-dimensional analysis space, and the pulls per bin from the null hypothesis (Fig. 3) were then examined. Event-by-event reconstructed data and Monte Carlo samples can be found in [62].

The LLH value for the data given each sterile neutrino hypothesis was calculated. No evidence for sterile neutrinos was observed. The best fit of the blind, shape-only analysis is at \( \Delta m^2 = 10 \text{ eV}^2 \) and \( \sin^2 2\theta_{24} = 0.56 \) with a log likelihood difference from the no-sterile-neutrino hypothesis of \( \Delta \text{LLH} = 1.91 \), corresponding to a \( p \) value
of 15%. Since the fit does not constrain flux normalization, LLH minima at $\Delta m^2 \gtrsim 5$ eV$^2$ are highly degenerate with the no-sterile-neutrino hypothesis. This is because the oscillation effect becomes a fast vacuumlike oscillation smeared out by the energy resolution of the detector, and thus changes the normalization but has no effect on shape.

Postunblinding tests highlighted two undesirable features of the shape-only analysis, both deriving from the degeneracy between high-$\Delta m^2$, fast oscillation hypotheses and changes in the flux normalization. First, because the high-$\Delta m^2$ space is not penalized by any prior, a log likelihood minimum in this region may not be uniquely defined under extensions of the search space. In some cases, slightly stronger exclusion limits can be found by increasing the search space to higher mass. Second, the degeneracy between normalization and mixing can lead to unphysical values for the normalization that compensate for the sterile neutrino oscillation effect. To avoid these ambiguities, an extension of the analysis (denoted rate $+$ shape) was developed to constrain the neutrino flux normalization using a prior with 40% uncertainty in the likelihood function, based on [44,63]. This results in a weakened exclusion relative to the blind analysis proposal. However, since it is more robust, we consider it our primary result. For the rate $+$ shape analysis, the best fit is at $\Delta m^2 = 10$ eV$^2$ and $\sin^2 2\theta_{24} = 0.50$, with a log likelihood difference from the no-sterile-neutrino hypothesis of $\Delta \text{LLH} = 0.75$, corresponding to a $p$ value of 47%. This minimum is unique under extension of the analysis space to higher masses, since the large $\Delta m^2$ region is no longer degenerate with the no-sterile-neutrino hypothesis. This was checked over an extended parameter space up to $\Delta m^2 = 100$ eV$^2$. The confidence interval for the shape-only and the rate $+$ shape analyses is shown in Fig. 4.

FIG. 2. Reconstructed energy distribution in data and Monte Carlo events for the no-sterile-neutrino hypothesis in the analysis.

FIG. 3. The statistical-only pulls (shape $+$ rate analysis) per reconstructed energy and zenith angle bin at the best nuisance parameter fit point for the no-sterile-neutrino hypothesis. The shown empty bins are those that were evaluated in the analysis but had no data events remaining following cuts.

FIG. 4. Results from IceCube sterile neutrino searches (regions to the right of the contours are excluded). The dot-dashed blue line shows the result of the original analysis based on shape alone, while the solid red line shows the final result with a normalization prior included to prevent degeneracies between the no-sterile-neutrino hypothesis and sterile neutrinos with masses outside the range of sensitivity. The dashed black line is the exclusion range derived from an independent analysis of data from the 59-string IceCube configuration.
A number of checks of the rate + shape analysis result were made (see [40]). The exclusion is found to be robust under tightening or loosening of the nuisance parameter priors by a factor of 2. Different strengths of the normalization constraint were tested, and the result was found to be relatively insensitive to values between 30% and 50%. The pulls on each continuous nuisance parameter were evaluated at all points in the LLH space and found to behave as expected. The contour was redrawn for each discrete nuisance variant and found to have good stability. The Wilks confidence intervals [64] were validated using Feldman-Cousins ensembles along the contour [39] and found to be accurate frequentist confidence intervals.

An independent search was conducted using the 59-string IceCube data [65,66], introduced previously, that also found no evidence of sterile neutrinos. The IC59 analysis, described in detail in [17], used different treatments for the systematic uncertainties and fitting methods and employed independent Monte Carlo samples that were compared to data using unique weighting methods. In particular, the event selection used for this data set had higher efficiency for low-energy neutrinos, using a threshold at 320 GeV, extending the sensitivity of the analysis to smaller $\Delta m^2$. However, detailed a posteriori inspections revealed that a background contamination from cosmic-ray-induced muons, on the level of 0.3% of the full sample, is largest in this region and could lead to an artificially strong exclusion limit. Furthermore, the energy reconstruction algorithm used in both analyses, which measures the level of bremsstrahlung and other stochastic light emission along the muon track, is vulnerable to subtle detector modeling issues and suffers degraded energy resolution in the low-energy region where most muons are minimum-ionizing tracks and a large fraction either starts or stops within the detector. It was therefore decided to exclude these events to avoid biasing the resulting exclusion regions. As a result of this a posteriori change, the IC59 analysis retains a comparable range of sensitivity to $\Delta m^2$ but the reach in $\sin^2 \theta_{24}$ is strongly reduced (see Fig. 4). However, we still present this result as it independently confirms the result presented here.

Discussion and conclusion.—Resonant oscillations due to matter effects produce distinctive signatures of sterile neutrinos in the large set of high-energy atmospheric neutrino data recorded by the IceCube neutrino observatory. The IceCube collaboration has performed searches for sterile neutrinos with $\Delta m^2$ between 0.1 and 10 eV$^2$. We have assumed a minimal set of flavor mixing parameters in which only $\theta_{24}$ is nonzero.

A nonzero value for $\theta_{24}$ changes the shape of the MSW resonance while increasing the total size of the disappearance signal [25]. As discussed in [27], among the allowed values of $\theta_{34}$ [8], the model with $\theta_{34} = 0$ presented here leads to the most conservative exclusion in $\theta_{24}$. The angle $\theta_{14}$ is tightly constrained by electron neutrino disappearance measurements [12], and nonzero values of $\theta_{14}$ within the allowed range do not strongly affect our result.

Figure 5 shows the current IceCube results at 90% (orange solid line) C.L. contour is shown with bands containing 68% (green) and 95% (yellow) of the 90% contours in simulated pseudoexperiments, respectively. (Bottom) The 99% (red solid line) C.L. contour is shown with bands containing 68% (green) and 95% (yellow) of the 99% contours in simulated pseudoexperiments, respectively. The contours and bands are overlaid on 90% C.L. exclusions from previous experiments [7–10], and the 99% C.L. allowed region from global fits to appearance experiments including MiniBooNE and LSND, assuming $|U_{e4}|^2 = 0.023$ [12] and $|U_{e4}|^2 = 0.027$ [13], respectively.
In any single realization of the experiment, deviations from the mean sensitivity are expected due to statistical fluctuations in the data and, to a considerably lesser extent, in the Monte Carlo data sets. Also shown is the 99% allowed region from a fit to the short baseline appearance experiments, including LSND and MiniBooNE, from [12,13,25], projected with $|U_{e4}|^2$ fixed to its world best-fit value according to global fit analyses [12,13,67]. This region is excluded at approximately the 99% confidence level, further increasing tension with the short baseline anomalies, and removing much of the remaining parameter space in the 3 + 1 model. We note that the methods developed for the IC59 and IC86 analyses are being applied to additional data sets, including several years of data already recorded by IceCube, from which we anticipate improvements in IceCube’s sterile neutrino sensitivity.

Note added.—Recently, an analysis using IceCube public data [68] was performed [69]. Though this independent analysis has a limited treatment of systematics, it follows the technique described here and in Refs. [40,41], and obtains comparable bounds. To allow for better reproduction of the result shown in this paper in the future, we have put forward a data release that incorporates detector systematics [62].
